Reactive Systems: Büchi Automata and LTL, part II

Timo Latvala

March 7, 2004
The algorithm of the previous lecture creates a graph stored in the set “nodes”. The nodes of this graph are labeled with formulas. Actually, from now on we are only interested in the formulas stored in the set “Old”.

It is now easy to obtain a Büchi automaton from this graph. (Using a slightly different Büchi automata definition than what has been used in this course so far.)

First of all a special initial state “init” is created. This state is the only state in $S^0$.

All nodes “$p \in \text{nodes}$” together with the initial state “init” are the states $S$ of the Büchi automaton.

The labeling of the arcs of the Büchi automaton can be derived from the formula labeling of states.

Namely, a state is compatible with a set of valuations as described below.

A valuation $v \in 2^{AP}$ is compatible with the label of a node $s$ iff:

- $\forall p \in AP$: if $p \in s.\text{Old}$ then $p \in v$, and

- $\forall p \in AP$: if $\neg p \in s.\text{Old}$ then $p \not\in v$. 

©2003 Keijo Heljanko, ©2004 Timo Latvala
There is an arc from a state $s \in S$ to a state $r \in S$ with a label $v \in 2^{{\mathcal{AP}}}$ iff

- $v$ is compatible with the valuation of $r$, and

- $s \in r.\text{Incoming}$.
The Büchi automaton class used is called generalized Büchi automata. In this class the acceptance component consist of several acceptance sets. The basic idea is that an accepting run should visit some accepting state from each acceptance set infinitely often.

More formally the acceptance component is $\mathcal{F} = \{F_1, F_2, \ldots, F_n\}$, where each $F_i \subseteq S$.

Now a generalized Büchi automaton $A$ accepts a run $r$ iff for all $F_i \in \mathcal{F}$: $\text{inf}(r) \cap F_i \neq \emptyset$.

Note that in the special case $\mathcal{F} = \emptyset$ all the infinite runs of the generalized Büchi automaton are accepting.
We will to rule out the use of case b) infinitely many times without also using case a) infinitely many times when proving the until formula $f_1 U f_2 \in sub(f)$. This is done by using one acceptance set for each until formula.
Assume, that all the until subformulas (subformulas of the form $g_1 U g_2$) are $f_1, f_2, \ldots, f_n$. Then the acceptance component $F = \{F_1, F_2, \ldots, F_n\}$, where:

For each $1 \leq i \leq n$ the state $s$ belongs to $F_i$ iff

- $right(f_i) \in s.\text{Old}$, ($g_2$ is proved) or
- $f_i \notin s.\text{Old}$ (we do NOT need to prove $f_i = g_1 U g_2$).

These together will assure that for each until formula $f_i$ either the right hand side is eventually proved, or that the until formula $f_i$ is not our proof obligation in state $s$.

Note also that if there are no until formulas, $F = \emptyset$.

Many of the emptiness checking algorithms, for example the nested depth first search, do not handle generalized Büchi automata. Thus most of the LTL to Büchi translation algorithms make a (non-generalized) Büchi automaton $A'$ out of the generalized Büchi automaton with the following procedure (which works for any generalized Büchi automaton).

The construction uses the same “counter trick” as the product construction of two Büchi automata.

Another option is to use e.g., a maximal strongly connected component based emptiness checking algorithm instead. (Tarjan’s MSCC algorithm with small modifications to detect accepting MSCCs.)
Definition 1 Let $\mathcal{A}$ be a generalized Büchi automaton $(\Sigma, S, S^0, \Delta, \mathcal{F})$, where $\mathcal{F} = \{F_1, F_2, \ldots, F_n\}$. We now define a (non-generalized) Büchi automaton $\mathcal{A}'$ by case analysis on $\mathcal{F}$:

- if $\mathcal{F} = \emptyset$ then $\mathcal{A}' = (\Sigma, S, S^0, \Delta, S)$,

- if $\mathcal{F} = \{F_1\}$ then $\mathcal{A}' = (\Sigma, S, S^0, \Delta, F_1)$,
• otherwise: \( \mathcal{F} = \{F_1, F_2, \ldots, F_n\} \), where \( n \geq 2 \): \( \mathcal{A}' = (\Sigma, S', S^0', \Delta', F_1') \), where:

- \( S' = S \times \{1, 2, \ldots, n\} \),

- \( S^0' = S^0 \times \{1\} \),

- \( \Delta' \) is defined as follows: \((s, i, a, (s', j)) \in \Delta' \) iff \((s, a, s') \in \Delta \) and
  
  \((s \notin F_i \text{ and } j = i) \lor (s \in F_i \text{ and } j = (i \mod n) + 1)) \), and

- \( F_1' = F_1 \times \{1\} \).
Now it holds that $L(\mathcal{A}') = L(\mathcal{A})$, and $\mathcal{A}'$ is never smaller than $\mathcal{A}$. In fact, in the worst case $\mathcal{A}'$ has $n$ times as many states as $\mathcal{A}$, where $n$ in the number of acceptance sets. This construction is essentially optimal (result due to H. Tauriainen).
Now we can prove some worst-case bounds on the automata size based on the presented translation algorithm.

Given an \(LT L\) formula \(f\) in negation normal form, for the generalized Büchi automaton \(A_f\) a (coarse) upper bound on the number of states it has is \(1 + 2^{(2 \cdot |sub(f)|)}\) states.

(There is the state “init”, plus at most as many different states as there are possible combinations of “Old” and “Next” sets, of which there are at most \(2^{(2 \cdot |sub(f)|)}\).)

**Theorem 2** Given an \(LT L\) formula \(f\) in negation normal form, the generalized Büchi automaton \(A_f\) has at most \(2^{O(|f|)}\) states.
Converting the generalized Büchi automaton to a non-generalized one we get (a coarse) upper bound of $|\text{sub}(f)| \cdot (1 + 2^{2 \cdot |\text{sub}(f)|})$ states. We thus get also the following result.

**Theorem 3** Given an LTL formula $f$ in negation normal form, the (non-generalized) Büchi automaton $A_f$ has at most $2^{O(|f|)}$ states.
There are quite a few highly optimized freely available LTL to Büchi automata translators available. Rolling your own can be educational, but not likely very effective in terms of the final Büchi automaton size.

The exponential blow-up in the construction is unavoidable when translating into Büchi automata. For example model checking the LTL formula

\[(\text{strong fairness}) \rightarrow (\text{property})\]

will exhibit this behavior, when one starts growing the value of \(n\) in

\[\text{strong fairness} = \bigwedge_{1 \leq i \leq n} (\Box \Diamond p_i \rightarrow \Box \Diamond q_i).\]

Such fairness assumptions often arise in model checking of liveness properties.
